3.3.2 Internal Standard Method
3.3.3 Standard Addition Method
3.4 Reliability Characteristics
3.4.1 Accuracy
3.4.2 Repeatability Precision (sr, RSDr)
3.4.3 Measurement Uncertainty
3.4.4 Reproducibility Precision (sR, RSDR)
3.4.5 Intermediate Precision
3.4.6 Limit of Determination
3.4.7 Reporting Low-level Values
3.4.8 Dichotomous Reporting
3.5 Controls
3.5.1 Control Charts
3.5.2 Injection Controls
3.5.3 Duplicate Controls
3.6 Confirmation of Analyte
4.0 Report (as applicable)

Identity, source, purity of reference material
Scope, applicability, nonapplicability
Recovery, levels, percent \( (n = 5 \text{ at each concentration level}) \)
Repeatability, RSD \(_r\) \( (n = 5 \text{ at each concentration level}) \)
Intermediate precision, RSD \(_i\) \( (n = 5 \text{ at each concentration level}) \)
Limit of determination

Because of the time and expense required for the determination of modern analytes such as pesticide residues, industrial contaminants, veterinary drugs, allergens, botanicals, dietary supplements, and alternative medicines in complex matrices, there is considerable interest in obtaining acceptable methods of analysis faster and cheaper. It has been suggested that accreditation of laboratories, internal quality control, and external proficiency exercises can improve laboratory performance to the point where interlaboratory validation is no longer an absolute necessity. To this end AOACI has been exploring alternatives to the full interlaboratory study design that requires the examination of a minimum of 5 matrices by 8 laboratories (see www.AOAC.org under method validation programs). These have included “minicollaborative” studies that reduced the required number of matrices and laboratories, the “Peer-Verified Methods Program” which merely required verification of the analytical parameters by a second laboratory, “Performance Tested Methods” for test kits, the developing e-CAM compiling program (www.AOAC.org/AOAC_e-CAM.pdf), and the International Union of Pure and Applied Chemistry (IUPAC) sanctioned single laboratory validation protocol (Pure & Appl. Chem. 74(5), 835-855(2002)).

The IUPAC single-laboratory protocol necessarily deals in generalities and specifically points out, “The total cost to the analytical community of validating a specific method through a collaborative trial and then verifying its performance attributes in the laboratories wishing to use it, is frequently less than when many laboratories all independently undertake single-laboratory validation of the same method.” The protocol also indicates that the degree of validation depends upon the status of the method in the analytical structure. At one extreme is the initial application of a well-established method in a laboratory that merely requires verification of the capability of that laboratory to achieve the published performance characteristics. The opposite extreme is the initial presentation of a new method or the initial application of an established method to a new matrix or application. Methods that are developed in response to a continued need for compliance, surveillance, and enforcement of laws and contracts involving a number of laboratories are expected to proceed to a multilaboratory validated status.

This AOACI document is intended to present guidelines for the evaluation of the initial use of a new or old method in a laboratory. It assumes that a proposed or
available method is fairly well developed, optimized, and stabilized, that it has been applied to some practical test samples with acceptable results, and that a description of the method and its initial performance results are available in some kind of document. The initiating or another laboratory must then decide if the demonstrated performance appears to be satisfactory for the same or for another purpose.

Although the output from method development is the input to method validation, method developers cannot expect much input from method validators. Although method validators may have had considerable experience in the analysis of practical analytical samples, they are not expected to have the basic knowledge to recommend improvement in methods, such as certain solvents as useful for extraction of certain classes of analytes or column-solvent combinations as useful for optimization of separations. Method developers are expected to bring methods to the point where they satisfy validation requirements.

By definition, single-laboratory validation does not provide any information on what values would be expected on examination of identical test samples by other laboratories. Therefore such methods probably would be used by regulatory agencies only for monitoring purposes—to explore compliance with laws and regulations unless the statutes under which they operate assign correctness to their results. Ordinarily such methods would not be used to bring a legal action or to settle a commercial dispute until their properties had been further explored in an environment provided by an interlaboratory collaborative study or a proficiency study utilizing that method. As stated in the FDA Center for Drug Evaluation and Research (CDER) “Reviewer Guidance/Validation of Chromatographic Methods” (November 1994), “Methods should be reproducible when used by other analysts, on other equivalent equipment, on other days and locations, and throughout the life of the drug product.”

1.0 Introduction

The primary purpose of validating a method of analysis is to show that the method is fit for its intended purpose. Some purposes are:

1. Determine how much of a valuable, necessary, or characteristic ingredient is present in a product.
2. Determine if a product meets specifications.
3. Determine if a product meets regulatory requirements.
4. Survey an environment to determine the presence and amount of a component, contaminant, or a nutrient.
5. Identify a product and/or its components.

The purposes usually answer the questions, “What is this product?” in the sense of its common or usual name, chemical identity, or components, and “How much of something [an analyte] is in this product [matrix]?”
At least at the initial stages of a problem, only a single or at most a very few laboratories require validation of a method of analysis. These circumstances include situations similar to the following:

1. Methods for research.
2. Only a few test samples are anticipated.
3. For quality control of a manufacturing process of a single item by a single producer,
4. Checking the reliability of a method imported from another source.
5. Rechecking the reliability of a previously used method after a period of disuse.
6. Situations where there is a lack of interest by other laboratories in participating in an interlaboratory validation exercise.
7. Multi-analyte, multi-matrix methods where a conventional interlaboratory validation exercise is impractical.

For the present purpose we assume:

1. We know or can assume the chemical identity of the material we are dealing with.
2. We have a specimen of the material that can be used as a reference to compare the signal produced by the analyte isolated from the product we are examining with the same signal produced by a known amount of the reference analyte (traceable to a stated reference).

If either or both of these requirement are not met, much useful information can still be obtained, but our information will be “floating” in the same sense as a ship at sea does not know where it is without landmarks to determine its position. If the identity of an analyte must be determined, not merely verified, a whole new dimension is added to the problem. This involves bringing in a laboratory or an individual with skill in determining chemical structure, a highly specialized, expensive, and time-consuming exercise.

It is often found during the initial experience with application or validation of a method that deficiencies appear, unexpected interferences emerge, reagents and equipment are no longer available, instruments must be modified, and other unanticipated problems require returning the method to a development phase. Frequently a method that functions satisfactorily in one laboratory fails to operate in the same manner in another. Often there is no clear-cut differentiation between development and validation and the two procedures constitute an iterative process. For that reason some aspects of method development that provide an insight into method performance, such as ruggedness, are included in this document.

In some cases it is impossible to set specific requirements because of unknown factors or incomplete knowledge. In such cases it is best to accept whatever information is generated during development and validation and rely upon the “improvements” that are usually forthcoming to asymptotically approach
performance parameters developed for other analytes in the same or in a similar class.

1.1 Definitions

1.1.1 Validation is the process of demonstrating or confirming the performance characteristics of a method of analysis.

This process of validation is separate from the question of acceptability or the magnitude of the limits of the characteristics examined, which are determined by the purpose of the application. Validation applies to a specific operator, laboratory, and equipment utilizing the method over a reasonable concentration range and period of time.

Typically the validation of a chemical method of analysis results in the specification of various aspects of reliability and applicability. Validation is a time-consuming process and should be performed only after the method has been optimized and stabilized because subsequent changes will require revalidation. The stability of the validation must also be verified by periodic examination of a stable reference material.

1.1.2 The method of analysis is the detailed set of directions, from the preparation of the test sample to the reporting of the results that must be followed exactly for the results to be accepted for the stated purpose.

The term “method of analysis” is sometimes assigned to the technique, e.g., liquid chromatography or atomic absorption spectrometry, in which case the set of specific directions is referred to as the “protocol.”

1.1.3 The performance characteristics of a method of analysis are the functional qualities and the statistical measures of the degree of reliability exhibited by the method under specified operating conditions.

The functional qualities are the selectivity (specificity), as the ability to distinguish the analyte from other substances; applicability, as the matrices and concentration range of acceptable operation; and degree of reliability, usually expressed in terms of bias as recovery, and variability as the standard deviation or equivalent terms (relative standard deviation and variance).

Measurements are never exact and the “performance characteristics of a method of analysis” usually reflect the degree to which replicate measurements made under the same or different conditions can be expected or required to approach the “true” or assigned values of the items or parameters being measured. For analytical chemistry, the item being measured is usually the concentration, with a statement of its uncertainty, and sometimes the identity of an analyte.
2.0 Single-Laboratory Validation Work

2.1 Preparation of the Laboratory Sample

Product and laboratory sampling are frequently overlooked aspects of analytical work because very often product sampling is not under the control of the laboratory but the sample is supplied by the customer. In this case, the customer assumes the responsibility of extrapolating from the analytical result to the original lot. If the laboratory is requested to sample the lot, then it must determine the purpose of the analysis and provide for random or directed sampling accordingly.

The laboratory is responsible for handling the sample in the laboratory to assure proper preparation with respect to composition and homogeneity and to assure a suitable analytical sample. The laboratory sample is the material received by the laboratory and it usually must be reduced in bulk and fineness to an analytical sample from which the test portions are removed for analysis. Excellent instructions for this purpose will be found in the “Guidelines for Preparing Laboratory Samples” prepared by the American Association of Feed Control Officials, Laboratory Methods and Service Committee, Sample Preparation Working Group (2000) (Ms Sharon Senesac, AFFCO Assistant Secretary-Treasurer, POBox 478, Oxford IN 47971) that cover the preparation of particularly difficult mineral and biological material. The improper or incomplete preparation of the analytical sample is an often overlooked reason for the nonreproducibility of analytical results.

If a laboratory prepares test samples for the purpose of validating a method, it should take precautions that the analyst who will be doing the validation is not aware of the composition of the test samples. Analysts have a bias, conscious or unconscious, of permitting knowledge of the identity or composition of a test sample to influence the result (J. AOAC Int. (2000) 83, 399-406).

2.2 Identification

Identification is the characterization of the substance being analyzed, including its chemical, mineral, or biological classification, as applicable. In many investigations the identity of the analyte is assumed and the correctness of the assumption is merely confirmed. With some products of natural origin, complete identification and characterization is not possible. In these cases identification often may be fixed by chemical, chromatographic, or spectrophotometric fingerprinting — producing a reproducible pattern of reactions or characteristic output signals (peaks) with respect to position and intensity.
For botanical products provide:
  the common or usual name of the item;
  the synonyms by which it is known;
  the botanical classification (variety, species, genus, family);
the active or characteristic ingredient(s) (name and Chemical Abstracts
Registry number or Merck Index number) and its chemical class. If the
activity is ascribable to a mixture, provide the spectral or chromatographic
fingerprint and the identity of the identifiable signals.

2.3 Method of Analysis or Protocol

The protocol or method of analysis is the set of permanent instructions for the
conduct of the method of analysis. The method of analysis that is finally used
should be the same as the one that was studied and revised as a result of
research, optimization, and ruggedness trials and edited to conform with
principles and practices for the production of Official Methods of Analysis of
AOAC International (OMA). At this point the text is regarded as fixed.
Substantive changes (those other than typographical and editorial) can only be
made by formal public announcement and approval.

This text should be in ISO-compatible format where the major heads
follow in a logical progression (e.g., Title, Applicability (Scope), Equipment,
Reagents, Text, Calculations, with the addition of any special sections required
by the technique, e.g., chromatography, spectroscopy). Conventions with
respect to reagents and laboratory operations should follow those given in the
section “Definitions and Explanatory Terms” which explains that “water is distilled
water,” reagents are of a purity and strength defined by the American Chemical
Society (note that these may differ from standards set in other parts of the world),
alcohol is the 95% aqueous mixture, and similar frequently used working
definitions.

AOAC-approved methods may be considered as “well-recognized test
methods” as used by ISO 17025. This document requires that those method
properties, which may be major sources of uncertainties of measurements, be
identified and controlled. In AOAC methods the following operations or
conditions, which may be major contributors to uncertainties, should be
understood to be within the following limits, unless otherwise specified more
strictly or more loosely:
  Weights within ±10% (but use actual weight for calculations)
  Volumes volumetric flasks, graduates, and transfer pipets (stated
    capacity with negligible uncertainty)
  Burets (stated capacity except in titrations)
  Graduated pipets — use volumes >10% of capacity
  Temperatures set to within ±2°
  pH within ±0.05 unit
  Time within ±5%
If the operational settings are within these specifications, together with any others derived from the supporting studies, the standard deviation obtained from these supporting studies in the same units as the reported result with the proper number of significant figures, usually 2 or 3, may be used as the standard measurement uncertainty.

2.3.1 Optimization

Prior to determining the performance parameters, the method should be optimized so that it is fairly certain that the properties of the “final method” are being tested. Validation is not a substitute for method development or for method optimization. If, however, some of the validation requirements have already been performed during the development phase, there is no need to repeat them for the validation phase. A helpful introduction is the AOACI publication “Use of Statistics to Develop and Evaluate Analytical Methods” by Grant T Wernimont. This volume has only three major chapters: the measurement process, intralaboratory studies, and interlaboratory studies. No simpler explanation in understandable chemical terms exists of the analysis of variance than that given in pages 28-31. It supplements, explaining in greater detail, the concepts exemplified in the popular “Statistical Manual of AOAC” by W. J. Youden. Other useful references are Appendix D and E of Official Methods of Analysis of AOAC International, 17th Edition (2000).

2.3.2 Reference standard

All chemical measurements require a reference point. Classical gravimetric methods depend on standard weights and measures, which are eventually traceable to internationally recognized (SI) units. But modern analytical chemistry depends on other physical properties in addition to mass and length, usually optical or electrical, and their magnitude is based upon an instrumental comparison to a corresponding physical signal produced from a known mass or concentration of the “pure” analyte. If the analyte is a mixture, the signals or components must be separated and the signal from each compound compared to the signal from a known mass or concentration of the pure material or expressed in terms of a single reference compound of constant composition.

All instrumental methods require a reference material, even those that measure an empirical analyte. An “empirical analyte” is an analyte or property whose value is not fixed as in stoichiometric chemical compounds but which is the result of the application of the procedure used to determine it; examples are moisture, ash, fat, carbohydrate (by difference), and fiber. It is a “method-dependent analyte”. Usually the reference material or “standard”, which are specific chemical compounds, can be purchased from a supplier of chemicals and occasionally from a national metrological institute. When used for reference
purposes, a statement should accompany the material certifying the identity, the purity and its uncertainty, how this was measured (usually by spectroscopy or chromatography), and its stability and storage conditions. If no reference material is available, as with many isolates from botanical specimens, an available compound with similar properties may serve as a surrogate standard — a compound that is stable and which behaves like the analyte but which is well resolved from it. Sometimes an impure specimen of the analyte must serve temporarily as the reference material until a purer specimen becomes available. The measured values assigned to empirical analytes are determined by strict adherence to all the details of the method of analysis. Even so, their bias and variability are usually larger (poorer) than chemically specified analytes. In some cases, as in determining the composition of milk by instrumental methods, the reference values for fat, protein, and lactose are established by use of reference methods. In routine operation, the bias and uncertainty of the final values are the combination of the uncertainties and bias correction arising from the routine operation with that of the reference values used for the calibration.

Modern instrumentation is complicated and its operation requires training and experience not only to recognize acceptable performance but also to distinguish unacceptable performance, drift, and deterioration on the part of the components. Continuous instruction and testing of the instruments and operators with in-house and external standards and proficiency exercises are necessary.

The records and report must describe the reference material, the source, and the basis for the purity statement (certification by the supplier is often satisfactory). If the reference material is hygroscopic, it should be dried before use either in a 100º C oven, if stable, or over a drying agent in a desiccator if not. The conversion factor of the analyte to the reference material, if different, and its uncertainty must be established, often through spectrophotometric or chromatographic properties such as absorptivity or peak height or area ratios.

For recovery experiments the reference standard should be the highest purity available. In the macro concentration range (defined as about 0.1-100%) the standard ordinarily approaches 100%; in the micro or trace (defined as μg/g to 0.1%) and ultramicro or ultratrace range (μg/g and below) the standard should be at least 95% pure. The purity of rare or expensive standards is often established, referenced, and transferred through an absorptivity measurement in a specific solvent. The impurities present should not interfere significantly with the assay.

2.3.3 Ruggedness Trial

Although the major factors contributing to variability of a method may be explored by the classical, one variable at a time procedure, examining the effect of less
important factors can be accomplished by a simpler Youden Ruggedness Trial (Youden, W.J. & Steiner, E.H. (1975) Statistical Manual of the Association of Official Analytical Chemists, pp. 50-55). This design permits exploring the effect of 7 factors in a single experiment requiring only 8 determinations. It also permits an approximation of the expected standard deviation from the variability of those factors that are “in control.” An example of exploring the extraction step of the determination of the active ingredient in a botanical is detailed in the Appendix.

2.3.4 Specific variables

If a variable is found to have an influence on the results, further method development is required to overcome the deficiency. For example, extraction of botanicals is likely to be incomplete and there are no reference materials available to serve as a standard for complete extraction. Therefore various techniques must be applied to determine when extraction is complete; reextraction with fresh solvent is the most common. Considerable experimentation also may be necessary to find the optimum conditions, column, and solvents for chromatographic isolation of the active ingredient(s).

   a. Analyte addition. — Addition of a solution of the active ingredient to the test sample and conducting the analysis is generally uninformative because the added analyte is already in an easily extractable form. The same is true for varying the volume of the extracting solvent. These procedures do not test the extractability of the analyte embedded in the cell structure. For this purpose, other variables must be tried, such as changing the solvent polarity or the extraction temperature.

   b. Reextraction of the extracted residue. — Reextraction after an original extraction will test for complete extraction by the original procedure. It will not test for complete extraction from intractable (unextractable) plant material. For this purpose a reagent that will destroy fibrous cellular material without damaging the active ingredient is required. If the analytes will not be destroyed or interfered with by cell wall disrupting or crude fiber reagents (1.25% H$_2$SO$_4$ and 1.25% NaOH) and are water soluble, use these solutions as extractives. But since the active ingredients are likely to contain compounds hydrolysable by these reagents, mechanical grinding to a very fine mesh will be the more likely choice.

   The efficiency of extraction is checked by application of the extract to TLC, GLC, or HPLC chromatography. Higher total extractables is not necessarily an indicator of better extraction. The quantification of the active ingredient(s) is the indicator of extraction. Many natural compounds are sensitive to light and the decrease of a component suggests that the effect of this variable should be investigated.

   c. Comparison with different solvents. — Solvents with different
polarities and boiling points will extract different amounts of extractives, but the amount of active ingredient(s) must be pursued by chromatographic separation or by specific reactions.

d. **Comparison with results from a different procedure.** — A number of analyte groups, e.g., pesticide residues, have several different standard methods available based on different principles to provide targets for comparison.

e. **System suitability checks.** — Chromatographic systems of columns, solvents (particularly gradients), and detectors are extremely sensitive to changes in conditions. Chromatographic properties of columns change as columns age and changes in polarity of solvents or temperature must be made to compensate. Therefore the specified properties of chromatographic systems in standard methods such as column temperatures and solvent compositions are permitted to be altered in order to optimize and stabilize the chromatographic output — peak height or area, peak resolutions, and peak shape. Similarly optical filters, electrical components of circuits, and mechanical components of instruments deteriorate with age and adjustments must be made to compensate. Specifications for instruments, and their calibration and operation must be sufficiently broad to accommodate these variations.

3. **Performance Characteristics**

The performance characteristics are required to determine if the method can be used for its intended purpose. The number of significant figures attached to the value of the characteristic generally indicates the reliability of these indices. They are generally limited by the repeatability standard deviation, $s_r$. In most analytical work requiring calibration the best relative $s_r$ that can be achieved is about 1%. This is equivalent to the use of 2 significant figures. However, in order to avoid loss of “accuracy” in averaging operations, carry one additional figure with all reported values, i.e., use at most 3 significant figures in reporting. This statement, however, does not apply to recorded raw data, such as weighing or instrument readings, calibration, and standardization, which should utilize the full reading capacity of the measurement scales. This exception is limited by the measurement scale with the least reading capacity.

The purpose of the analysis determines which attributes are important and which may be less so.

3.1 **Applicability (Scope)**

A method must demonstrate acceptable recovery and repeatability with representative matrices and concentrations to which it is intended to be applied. For single materials, use at least 3 typical specimens, at least in duplicate, with
different attributes (appearance, maturity, varieties, age). Repeat the analyses at least one day later. The means should not differ significantly and the repeatability should approximate those listed in §3.4.2 for the appropriate concentration. If the method is intended to be applied to a single commodity, e.g., fruits, cereals, fats, use several representative items of the commodity with a range of expected analyte concentrations. If the method is intended to apply to “foods” in general, select representative items from the food triangle (Sullivan, D.M. and Carpenter, D.E. (1993) “Methods of Analysis for Nutrition Labeling” AOAC International, Gaithersburg MD 20877, pp. 115-120). In the case of residues, the matrices are generalized into categories such as “fatty foods” and “nonfatty foods” that require different preliminary treatments to remove the bulk of the “inert” carrier. In all cases, select test materials that will fairly represent the range of composition and attributes that will be encountered in actual practice. Applicability may be inferred to products included within tested extremes but cannot be extrapolated to products outside the tested limits.

Similarly the range of expected concentrations should be tested in a number of typical matrices, spiking if necessary, to ensure that there is no interaction of analyte with matrix.

Semipermanent “house standards” for nutrients often can be prepared from a homogeneous breakfast cereal for polar analytes and from liquid monounsaturated oil like olive oil for nonpolar analytes for use as concurrent controls or for fortification.

The authority for the authenticity of botanical specimens and their source and the origin or history of the test materials must be given.

The determination of freedom from the effects of interfering materials is tested under selectivity, §3.2, and properties related to the range of quantification of the target analyte are tested under the reliability characteristics, §3.4.

3.2 Selectivity

The term selectivity is now generally preferred by IUPAC over specificity. Selectivity is the degree to which the method can quantify the target analyte in the presence of other analytes, matrices, or other potentially interfering materials. This is usually achieved by isolation of the analyte through selective solvent extraction, chromatographic or other phase separations, or by application of analyte-specific techniques such as biochemical reactions (enzymes, antibodies) or instrumentation (NMR, infrared or mass spectrometry).

Methods must be tested in the presence of accompanying analytes or matrices most likely to interfere. Matrix interference is usually eliminated by
extraction procedures and the desired analyte is then separated from other extractives by chromatography or solid-phase extraction. Nevertheless, many methods for low-level analytes still require a matrix blank because of the presence of persistent, nonselective background.

The most useful separation technique is chromatography and the most important requirement is resolution of the desired peak from accompanying peaks. Resolution, $R_s$, is expressed as a function of both the absolute separation distance expressed as retention times (minutes) of the two peaks, $t_1$ and $t_2$, and the baseline widths, $W_1$ and $W_2$, of the analyte and nearest peak, also expressed in terms of times, as

$$R_s = \frac{2(t_2 - t_1)}{(W_1 + W_2)}.$$

Baseline widths are measured by constructing tangents to the two sides of the peak band and measuring the distance between the intersection of these tangents with the baseline or at another convenient position such as half-height. A resolution of at least 1.5 is usually sought and one of 1.0 is the minimum usable separation. The U.S. Food and Drug Administration (FDA) suggests an $R_s$ of at least 2 for all compounds accompanying active drug dosage forms, including hydrolytic, photolytic, and oxidative degradation products. In addition, the isolated analyte should show no evidence of other compounds when chromatographed on other systems consisting of different columns and solvents, or when examined by techniques utilized for specificity (infra-red, nuclear magnetic resonance (NMR), or mass spectrometry (MS)). These requirements were developed for synthetic drug substances, and must be relaxed for the families of compounds commonly encountered in foods and botanical specimens to a resolution of 1.5 from adjacent nontarget peaks.

If the product is mixed with other substances, the added substances must be tested to ensure that they do not contain any material that will interfere with the identification and determination of the analyte sought. If the active constituent is a mixture, the necessity for separation of the ingredients is a decision related to the complexity of the potential separation, the constancy of the relationship of the components, and the relative biological activity of the constituents.

### 3.3 Calibration

Modern instrumental methods depend upon the comparison of a signal from the unknown concentration of an analyte to that from a known concentration of the same or similar analyte. This requires the availability of a reference standard, §2.2.2. The simplest calibration procedure requires preparation of a series of standard solutions from the reference material, by dilution of a stock solution, covering a reasonable range of signal response from the instrument. Six to 8 points, approximately equally spaced over the concentration range of interest, performed in duplicate but measured at random (to avoid confusing nonlinearity
with drift) is a suitable calibration pattern. Fit the calibration line (manually or numerously statistical and spreadsheet programs are available) and plot the residuals (the difference of the experimental points from the fitted line) as a function of concentration. An acceptable fit produces a random pattern of residuals with a 0 mean. For checking linearity, prepare the individual solutions by dilution from a common stock solution to avoid the random errors likely to be introduced from weighing small (mg) quantities for individual standards.

As long as the purity of the reference material is 95% or greater, as determined by evaluating secondary peaks or spots in gas, liquid, or thin-layer chromatography or other quantitative technique, the impurities contributes little to the final variance at micro- and ultramicro concentrations and may be neglected. (Recovery trials, however, require greater purity or correction for the impurities.) The identity of the material used as the reference material, however, is critical. Any suggestion of nonhomogenity such as multiple or distorted peaks or spots, insoluble residue, or appearance of new peaks on standing requires further investigation of the identity of the standard.

Similarly, certified volumetric glassware may also be used after initial verification of their stated capacity by weighing the indicated volume of water for flasks and the delivered volume for pipets and burets and converting the weight to the volume delivered.

Do not use serological pipets at less than 10% of their graduated capacity. Check the stability of the stock and initial diluted solutions, stored at room or lower temperatures, by repeating their measurements several days or weeks later. Prepare the most dilute solutions fresh as needed from more concentrated, stable solutions in most cases. Bring solutions stored at refrigerator or lower temperatures to room temperature before opening and using them.

Plot the signal response against the concentration. A linear response is desirable as it simplifies the calculations, but it is not necessary nor should it be regarded as a required performance characteristic. If the curve covers several orders of magnitude, weighted regression, easily handled by computer programs, may be useful. Responses from electrochemical and immunological methods are exponential functions, which often may be linearized by using logarithms. Some instruments perform signal-to-concentration calculations automatically using disclosed or undisclosed algorithms. If the method is not used routinely, several standards should accompany the test runs. If the method is used routinely, the standard curve should be repeated daily or weekly, depending on its stability. Repeat the standard curve as frequently as necessary with those instruments where drift is a significant factor.

A high correlation coefficient (e.g., >0.99) is often recommended as evidence of goodness of fit. Such use of the correlation coefficient as a test for linearity is incorrect (Analytical Methods Committee, Analyst (1988) 113, 1469-
1471; (1994) 119, 2363). Visual examination is usually sufficient to indicate linearity or nonlinearity, or use the residual test, §3.3.

If a single (parent or associated) compound is used as the reference material for a series of related compounds, give their relationship in structure and response factors.

Note that the calibration is performed directly with the analyte reference solutions. If these reference solutions are carried through the entire procedure, losses in various steps of the procedure cannot be explored but are automatically compensated for. Some procedures require correction of the final result for recovery. When this is necessary, use a certified reference material, a “house” standard, or analyte added to a blank matrix conducted through the entire method for this purpose. If several values are available from different runs, the average is usually the best estimate of recovery. Differences of calibration curves from day to day may be confused with matrix effects because they are often of the same magnitude.

3.3.1 External Standard Method

The most common calibration procedure utilizes a separately prepared calibration curve because of its simplicity. If there is a constant loss in the procedure, this is handled by a correction factor, as determined by conducting a known amount of analyte through the entire procedure. The calculation is based on the ratio of the response of equal amounts of the standard or reference compound to the test analyte. This correction procedure is time consuming and is used as a last resort since it only improves accuracy at the expense of precision. Alternatives are the internal standard procedure, blank matrix process, and the method of standard addition.

If the method is intended to cover a substantial range of concentrations, prepare the curve from a blank and 5 or 7 approximately equally spaced concentration levels and repeat on a second day. Repeat occasionally as a check for drift. If an analyte is examined at substantially different concentration levels, such as pesticide residues and formulations, prepare separate calibration curves covering the appropriate range to avoid excessive dilutions. In such cases, take care to avoid cross contamination. However, if the analyte always occurs at or near a single level as in a pharmaceutical, a 2-point curve may be used to bracket the expected level, or even a single standard point, if the response over the range of interest is approximately linear. By substituting an analyte-free matrix preparation for the blank, as might be available from pesticide or veterinary drug residue studies or the excipients from a pharmaceutical, a calibration curve that automatically compensates for matrix interferences can be prepared.
3.3.2 Internal Standard Method

The internal standard method requires the addition of a known amount of a compound that is easily distinguished from the analyte but which exhibits similar chemical properties. The response ratio of the internal standard to a known amount of the reference standard of the analyte of interest is determined beforehand. An amount of internal standard similar to that expected for the analyte is added at an early stage of the method. This method is particularly useful for addition to the eluate from an HPLC separation when the fractions are held in an autosampler that is run overnight, where it compensates for any losses of solvent by evaporation. An internal standard is also frequently used in GLC residue methods where many analytes with similar properties are frequently encountered.

3.3.3 Standard Addition Method

When the matrix effect on an analyte is unknown or variable, the method of standard additions is useful. Make measurements on the isolated analyte solution and add a known amount of the standard analyte at the same level and at twice or three (or known fractions) times the original level. Plot the signal against the concentration with the initial unknown concentration set at 0. Extrapolate the line connecting the measured responses back to 0 response and read the concentration value off the (negative) x-axis. The main assumption is that the response is linear in the working region. This method is used most frequently with emission spectroscopy, electrochemistry, and radiolabeled isotopes in mass spectrometric methods.

3.4 Reliability Characteristics

These are the statistical measures of how good the method is. Different organizations use different terms for the same concept. The important questions are:

How close is the reported value to the true, reference, or accepted value?
How close are repeated values to each other as determined in the same or different laboratories?
What is the smallest amount or concentration that can be recognized or measured?

Recently accreditation organizations have been requesting the calculation of the parameter “Measurement Uncertainty” (MU). This is a term indicative of the reliability of the particular series of measurements being reported. The standard uncertainty is equal to the standard deviation of the series of measurements of the analyte. The expanded uncertainty is two times the standard uncertainty and is expected to encompass about 95% of similar future measurements. If too few values are available in a measurement series to calculate a stable MU, the standard deviation obtained from the validation study within the laboratory, \( s_r \), may be substituted, if it covered the same or similar analyte/matrix/concentration range. If a collaboratively studied method is being validated for use within a laboratory, the standard deviation among-laboratories, \( s_R \), reported for the method from the study should be used to determine if the anticipated measurement uncertainty will be satisfactory for the intended purpose, assuming satisfactory repeatability as demonstrated by control charts or proficiency testing. In fact, the determination of the reliability characteristics in the validation study should not be undertaken until the developmental work demonstrates that the data are repeatable and in statistical control.

The Codex Alimentarius, an international body organized by the Food and Agricultural Organization (FAO) and the World Health Organization (WHO) of the United Nations (UN) to recommend international food standards to governments, suggests the following “Guidelines for the Assessment of the Competence of Testing Laboratories Involved in the Import and Export Control of Food” (FAO, Rome, Italy, CAC/GL 27-1997) for laboratories:

- Comply with the general competence criteria of ISO 17025;
- Participate in proficiency testing schemes for food analysis;
• Utilize validated methods; and
• Utilize internal quality control procedures.

3.4.1 Accuracy

The term “accuracy” has been given so many meanings that it is better to use a more specific term. Ordinarily it means closeness of the test result to the “true” or accepted value. But the test result can be an individual value, the average of a set of values, or the average of many sets of values. Therefore, whenever the term is used, the number of values it represents and their relationship must always be stated, e.g., as an individual result, as the average of duplicates or n replicates, or as the average of a set of a number of trials. The difference of the reported value from the accepted value, whether it is an individual value, an average of a set of values, or the average of a number of averages, or an assigned value, is the bias under the reported conditions. The frequently used term for bias or “accuracy” when the average of a set of values is reported is “trueness”.

The fraction or percentage of the analyte that is recovered when the test sample is conducted through the entire method is the recovery. The best reference materials for determining recovery are analyte-certified reference materials (CRMs) distributed by national metrological laboratories, but in most cases material certified by a commercial supplier must be accepted. Occasionally standards are available from a government agency, such as pesticides from the Environmental Protection Agency (EPA). They are rarely, if ever, available in the matrix of interest but rather as a solution in a convenient solvent with a stated concentration and uncertainty. Such reference materials must then be tested in the matrix of interest. Even rarer is an isotopically labeled analyte that can be easily followed by isotopic analytical techniques.

The available certified or commercial analyte standard, diluted if necessary, is added to typical analyte-free matrices at levels about 1x or 2x the expected concentration. Analyte-free matrices for residues are obtained from growers who certify that the chemical is not used in their cultivation, growth, or feeding and verified analytically. They may also be obtained from the residues of previously extracted materials or from test samples shown to be negative for the analyte.

If an analyte-free matrix is not available, the analyte standard is added to separate test portions and the recovery is calculated from the base determined by the method of addition, §3.3.3. Run the set of such controls with each set of test samples. If a sufficient number of batches are expected to be run (at least 20-30), the % recovery can be plotted against the run number as the basis for a control chart. Recovery also can be obtained as a byproduct of the precision determinations, §3.4.2 and §3.4.4.
Acceptable recovery is a function of the concentration and the purpose of the analysis. Some acceptable recovery requirements for individual assays are as follows:

<table>
<thead>
<tr>
<th>Concentration</th>
<th>Recovery limits</th>
</tr>
</thead>
<tbody>
<tr>
<td>100 %</td>
<td>98-101%</td>
</tr>
<tr>
<td>10 %</td>
<td>95-102%</td>
</tr>
<tr>
<td>1 %</td>
<td>92-105%</td>
</tr>
<tr>
<td>0.1 %</td>
<td>90-108%</td>
</tr>
<tr>
<td>0.01%</td>
<td>85-110%</td>
</tr>
<tr>
<td>10 ug/g (ppm)</td>
<td>80-115%</td>
</tr>
<tr>
<td>1 ug/g</td>
<td>75-120%</td>
</tr>
<tr>
<td>10 ug/kg (ppb)</td>
<td>70-125%</td>
</tr>
</tbody>
</table>

The Codex Alimentarius Volume 3 “Residues of Veterinary Drugs in Foods” 2nd ed. (1993), Joint FAP/WHO Food Standards Programme, FAO, Rome Italy, p 59, suggests the following limits for residues of veterinary drugs in foods:

<table>
<thead>
<tr>
<th>Concentration</th>
<th>Acceptable Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 ug/kg</td>
<td>50 – 120 %</td>
</tr>
<tr>
<td>1 &lt;10 ug/kg</td>
<td>60 – 120 %</td>
</tr>
<tr>
<td>10 &lt;100 ug/kg</td>
<td>70 – 110 %</td>
</tr>
<tr>
<td>100 ug/kg</td>
<td>80 – 110 %</td>
</tr>
</tbody>
</table>

These limits may be modified as needed in view of the variability of individual results or which set of regulatory requirements are referenced. (As a rough guide to typical performance, about 95% of normally distributed typical results in a single laboratory at 1 ug/g will fall within 80-120% of the mean.) In the case of the examination of the general USDA pesticide residue proficiency study, limits of 50–150% were applied; the USFDA acceptability criterion for recovery of drug residues at the 10 ppb level is 70–120%. Generally, however, recoveries less than 60–70% should be subject to investigations leading to improvement and average recoveries greater than 110% suggest the need for better separations. Most important, recoveries greater than 100% must not be discarded as impossible. They are the expected positive side from a typical distribution of analytical results from analytes present at or near 100% that are balanced by equivalent results on the negative side of the mean.

If an extraction of active ingredient from a matrix with a solvent is used, test extraction efficiency by reextracting the (air-dried) residue and determining the active ingredient(s) in the residue by the method.
The number of units to be used to establish bias is arbitrary, but the general rule is the more independent “accuracy” trials, the better. The improvement, as measured by the width of the confidence interval for the mean, follows the square root of the number of trials. Once past 8-10 values, improvement comes slowly. To fully contribute, the values must be conducted independently, i.e., nonsimultaneously, throwing in as many environmental or spontaneous differences as possible, such as different analysts, instruments, sources of reagents, time of day, temperature, barometric pressure, humidity, power supply voltage, etc. Each value also contributes to the within-laboratory precision as well. A reasonable compromise is to obtain 10 values from a reference material, a spiked matrix, or by the method of standard addition scattered over several days or in different runs as the basis for checking bias or recovery. By performing replicates, precision is obtained simultaneously. Precision obtained in such a manner is often termed “intermediate precision” because its value is between within-laboratory and among-laboratory precision. When reported, the conditions that were held constant and those that were varied must be reported as well.

Note that the series of determinations conducted for the method of addition are not independent because they are probably prepared from the same standard calibration solution, same pipets, and are usually conducted almost simultaneously. This is satisfactory for their intended purpose of providing an interrelated function, but it is not satisfactory for a precision function estimation intended for future use.

Related to recovery is the matter of reporting the mean corrected or not corrected for recovery. Unless specifically stated in the method to correct or not, this question is usually considered a “policy” matter and is settled administratively outside the laboratory by a regulatory pronouncement, informal or formal agreement, or by contract. If for some reason a value closest to theory is needed, correction is usually applied. If a limit or tolerance has been established on the basis of analytical work with the same method correlated with “no effect” levels, no correction should be applied because it has already been used in setting the specification. Corrections improve “accuracy” at the expense of impairing precision because the variability of both the determination and the recovery are involved.

When it is impossible to obtain an analyte-free matrix to serve as a base for reporting recovery, two ways of calculating recovery must be distinguished: (1) Total recovery based on recovery of the native plus added analyte, and (2) marginal recovery based only on the added analyte (the native analyte is subtracted from both the numerator and denominator). Usually total recovery is used unless the native analyte is present in amounts greater than about 10% of the amount added, in which case use the method of addition, §3.3.3.
When the same analytical method is used to determine both the concentration of the fortified, $C_f$, and unfortified, $C_u$, test samples, the % recovery is calculated as

$$\text{% recovery} = \frac{(C_f - C_u) \times 100}{C_a},$$

where $C_a$ is the calculated (not analyzed) concentration of analyte added to the test sample. The concentration of added analyte should be no less that the concentration initially present and the response of the fortified test sample must not exceed the highest point of the calibration curve. Both fortified and unfortified test samples must be treated identically in the analysis.

### 3.4.2 Repeatability Precision ($s_r, \text{RSD}_r$)

Repeatability refers to the degree of agreement of results when conditions are maintained as constant as possible with the same analyst, reagents, equipment, and instruments performed within a short period of time. It usually refers to the standard deviation of simultaneous duplicates or replicates, $s_r$. It is the best precision that will be exhibited by a laboratory but it is not necessarily the laboratory’s typical precision. Theoretically the individual determinations should be independent but this condition is practically impossible to maintain when determinations are conducted simultaneously and therefore this requirement is generally ignored.

To obtain a more representative value for the repeatability precision perform the simultaneous replicates at different times (but the same day), on different matrices, at different concentrations. Calculate the standard deviation of repeatability from at least 5 pairs of values obtained from at least one pair of replicates analyzed with each batch of analyses for each pertinent concentration level that differs by approximately an order of magnitude and conducted at different times. The object is to obtain representative values, not the “best value”, for how closely replicates will check each other in routine performance of the method. Therefore these sets of replicate analyses should be conducted at least in separate runs and preferably on different days. The repeatability standard deviation varies with concentration, $C$ expressed as a mass fraction. Acceptable values approximate the values in the following Table or calculated by the formula:

$$\text{RSD}_r = C^{-0.15}$$

unless there are reasons for using tighter requirements.
<table>
<thead>
<tr>
<th>Concentration</th>
<th>Repeatability (RSD$_r$)</th>
</tr>
</thead>
<tbody>
<tr>
<td>100 %</td>
<td>1 %</td>
</tr>
<tr>
<td>10 %</td>
<td>1.5%</td>
</tr>
<tr>
<td>1 %</td>
<td>2 %</td>
</tr>
<tr>
<td>0.1 %</td>
<td>3 %</td>
</tr>
<tr>
<td>0.01%</td>
<td>4 %</td>
</tr>
<tr>
<td>10 ug/g (ppm)</td>
<td>6 %</td>
</tr>
<tr>
<td>1 ug/g</td>
<td>8 %</td>
</tr>
<tr>
<td>10 ug/kg (ppb)</td>
<td>15 %</td>
</tr>
</tbody>
</table>

Acceptable values for repeatability are between $\frac{1}{2}$ and 2 times the calculated values. Alternatively, a ratio can be calculated of the found value for RSD$_r$ to that calculated from the formula designated as HORRAT$_r$. Acceptable values for this ratio are typically 0.5 to 2:

$$\text{HORRAT}_r = \frac{\text{RSD}_r (\text{found, } \%)}{\text{RSD}_r (\text{calculated, } \%)}$$

The term “repeatability” is applied to parameters calculated from simultaneous replicates and this term representing minimum variability is equated to the “within-laboratory” parameter (standard deviation, variance, coefficient of variation, relative standard deviation) of the precision model equation. It should be distinguished from a somewhat larger within-laboratory variability that would be induced by non-simultaneous replicates conducted in the same laboratory on identical test samples on different days, by different analysts, with different instruments and calibration curves, and with different sources of reagents, solvents, and columns. When such an “intermediate” within-laboratory precision (standard deviation, variance, coefficient of variation, relative standard deviation) is used, a statement of the conditions that were not constant must accompany it. These within-laboratory conditions have also been called within-laboratory reproducibility, an obvious misnomer.

3.4.3 Measurement Uncertainty

Accreditation organizations have been requesting laboratories to have a parameter designated as “measurement uncertainty” associated with methods that the laboratory utilizes. The official metrological definition of measurement uncertainty is “a parameter associated with the result of a measurement that characterizes the dispersion of values that could reasonably be attributed to the measurand.” A note indicates, “the parameter may be, for example, a standard deviation (or a given multiple of it), or the width of a confidence interval.”

Of particular pertinence is the fact that the parameter applies to a measurement and not to a method (see §3.4). Therefore “standard” measurement uncertainty is the standard deviation or relative standard deviation.
from a series of simultaneous measurements. “Expanded” uncertainty is typically twice the standard uncertainty and is considered to encompass approximately 95% of future measurements. This is the value customarily used in determining if the method is satisfactory for its intended purpose although it is only an approximation because theoretically it applies to the unknown “true” concentration.

Since the laboratory wants to know beforehand if the method will be satisfactory for the intended purpose, it must use the parameters gathered in the validation exercises for this purpose, substituting the measurement values for the method values after the fact. As pointed out by M. Thompson (Analyst (2000) 125, 2020-5; see Inside Lab. Mgmt. (2001) 5(2), 5) a ladder of errors exist for this purpose.

Duplicate error (a pair of tests conducted simultaneously)
Replicate or run error (a series of tests conducted in the same group)
Within-laboratory error (all tests conducted by a laboratory)
Between-laboratory error (all tests by all laboratories)

As we go down the series, the possibility of more errors being included is increased until a maximum is reached with the all inclusive reproducibility parameters. Thompson estimates the relative magnitude of the contribution of the primary sources of error as follows

<table>
<thead>
<tr>
<th>Level of variation</th>
<th>Separate</th>
<th>Cumulative</th>
</tr>
</thead>
<tbody>
<tr>
<td>Repeatability</td>
<td>1.0</td>
<td>1.0</td>
</tr>
<tr>
<td>Runs</td>
<td>0.8</td>
<td>1.3</td>
</tr>
<tr>
<td>Laboratories</td>
<td>1.0</td>
<td>1.6</td>
</tr>
<tr>
<td>Methods</td>
<td>1.5</td>
<td>2.2</td>
</tr>
</tbody>
</table>

Ordinarily only one method exists or is being validated so we can ignore the last line. Equating duplicates to replicability, runs to within-laboratory repeatability, and laboratories to among-laboratories reproducibility, Thompson points out that the three sources of error are roughly equal and not much improvement in uncertainty would result from improvement in any of these sources. In any case, the last column gives an approximate relative relationship of using the standard deviation at any point of the ladder as the basis for the uncertainty estimate prior to the actual analytical measurements.

In the discussion of uncertainty it must be noted that bias as measured by recovery is not a component of uncertainty. Bias (a constant) should be removed by subtraction before calculating standard deviations. Differences in bias as exhibited by individual laboratories become a component of uncertainty through the among-laboratory reproducibility. The magnitude of the uncertainty depends on how it is used — comparisons within a laboratory, with other laboratories, and
even with other methods. Each component adds uncertainty. Furthermore, uncertainty stops at the laboratory’s edge. If only a single laboratory sample has been submitted and analyzed, there is no basis for estimating sampling uncertainty. Multiple independent samples are required for this purpose.

3.4.4 Reproducibility Precision ($s_R$, $RSD_R$)

Reproducibility precision refers to the degree of agreement of results when operating conditions are as different as possible. It usually refers to the standard deviation ($s_R$) or the relative standard deviation ($RSD_R$) of results on the same test samples by different laboratories and therefore is often referred to as “between-laboratory precision” or the more grammatically correct “among-laboratory precision.” It is expected to involve different instruments, different analysts, different days, and different laboratory environments and therefore it should reflect the maximum expected precision exhibited by a method. Theoretically it consists of two terms: the repeatability precision (within-laboratory precision, $s_r$) and the “true” between-laboratory precision, $s_L$. The “true” between-laboratory precision, $s_L$, is actually the pooled constant bias of each individual laboratory, which when examined as a group is treated as a random variable. The between-laboratory precision too is a function of concentration and is approximated by the Horwitz equation, $s_R = 0.02C^{0.85}$. The AOAC/IUPAC protocol for interlaboratory studies requires the use of a minimum of 8 laboratories examining at least 5 materials to obtain a reasonable estimate of this variability parameter, which has been shown to be more or less independent of analyte, method, and matrix.

By definition $s_R$ does not enter into single-laboratory validation. However, as soon as a second (or more) laboratory considers the data, the first question that arises involves reanalysis by that second laboratory: “If I had to examine this or similar materials, what would I get?” As a first approximation, in order to answer the fundamental question of validation — fit for the intended purpose — assume that the recovery and limit of determination are of the same magnitude as the initial effort. But the variability, now involving more than one laboratory, should be doubled because variance, which is the square of differences, is involved, which magnifies the effect of this parameter. Therefore we have to anticipate what another laboratory would obtain if it had to validate the same method. If the second laboratory on the basis of the doubled variance concludes the method is not suitable for its intended purpose, it has saved itself the effort of revalidating the method.

In the absence of such an interlaboratory study, the interlaboratory precision may be estimated from the concentration as indicated in the following Table or by the formula (unless there are reasons for using tighter requirements):

$$RSD_R = 2C^{-0.15}.$$
Or

\[ S_R = 0.02C^{0.85} \]

<table>
<thead>
<tr>
<th>Concentration, C</th>
<th>Reproducibility (RSDR)</th>
</tr>
</thead>
<tbody>
<tr>
<td>100 %</td>
<td>2 %</td>
</tr>
<tr>
<td>10 %</td>
<td>3 %</td>
</tr>
<tr>
<td>1 %</td>
<td>4 %</td>
</tr>
<tr>
<td>0.1 %</td>
<td>6 %</td>
</tr>
<tr>
<td>0.01%</td>
<td>8 %</td>
</tr>
<tr>
<td>10 ug/g (ppm)</td>
<td>11 %</td>
</tr>
<tr>
<td>1 ug/g</td>
<td>16 %</td>
</tr>
<tr>
<td>10 ug/kg (ppb)</td>
<td>32 %</td>
</tr>
</tbody>
</table>

Acceptable values for reproducibility are between ½ and 2 times the calculated values. Alternatively a ratio can be calculated of the found value for RSD\(R\) to that calculated from the formula designated as HORRAT\(R\). Acceptable values for this ratio are typically 0.5 to 2:

\[ \text{HORRAT}_R = \text{RSD}_R \text{ (found, %)}/\text{RSD}_R \text{ (calculated, %)} \]

As stated by Thompson and Lowthian ("The Horwitz Function Revisited" J. AOAC Int. (1997) 80, 676-679), "Indeed, a precision falling within this 'Horwitz Band' is now regarded as a criterion for a successful collaborative trial."

The typical limits for HORRAT values may not apply to indefinite analytes (enzymes, polymers), physical properties, or to the results from empirical methods expressed in arbitrary units. Better than expected results are often reported at both the high (>10%) and low (<E-8) ends of the concentration scale. Better than predicted results can also be attained if extraordinary effort or resources are invested in education and training of analysts and in quality control.

### 3.4.5 Intermediate precision

The precision determined from replicate determinations conducted within a single laboratory not simultaneously, i.e., on different days, with different calibration curves, with different instruments, by different analysts, etc. is called intermediate precision. It lies between the within- and among-laboratories precision, depending on the conditions that are varied. If the analysis will be conducted by different analysts, on different days, on different instruments, conduct at least 5 sets of replicate analyses on the same test materials under these different conditions for each concentration level that differs by approximately an order of magnitude.
3.4.6 Limit of Determination

The limit of determination is a very simple concept: It is the smallest amount or concentration of an analyte that can be estimated with acceptable reliability. But this statement contains an inherent contradiction: the smaller the amount of analyte measured, the greater the unreliability of the estimate. As we go down the concentration scale, the standard deviation increases to the point where a substantial fraction of values of the distribution of results overlaps 0 and false negatives appear. Therefore the definition of the limit comes down to a question of what fraction of values are we willing to tolerate as false negatives.

Thompson and Lowthian (loc. cit.) consider the point defined by $RSD_R = 33\%$ as the upper bound for useful data, derived from the fact that $3RSD_R$ should contain 100\% of the data from a normal distribution. This is equivalent to a concentration of about $8 \times 10^{-9}$ (as a mass fraction) or 8 ng/g (ppb). Below this level false negatives appear and the data goes “out of control”. From the formula, this value is also equivalent to an $RSD_r \approx 20\%$. The penalty for operating below the equivalent concentration level is the generation of false negative values. Such signals are generally accepted as negative and are not repeated.

An alternative definition of the limit of detection and limit of determination is based upon the variability of the blank. The blank value, $x_{Bl}$, plus three times the standard deviation of the blank ($x_{Bl} + 3s_{Bl}$) is taken as the detection limit and the blank value plus 10 times the standard deviation of the blank ($x_{Bl} + 10s_{Bl}$) is taken as the determination limit. The problem with this approach is that the blank is often difficult to measure or is highly variable. Furthermore, the value determined in this manner is independent of the analyte. If blank values are accumulated over a period of time, the average is likely to be fairly representative as a basis for the limits and will probably provide a value of the same magnitude as that derived from the relative standard deviation formulae.

The detection limit is only useful for control of undesirable impurities that are specified as “not more than” a specified low level and for low-level contaminants. Useful ingredients must be present at high enough concentrations to be functional. The specification level must be set high enough in the working range that acceptable materials do not produce more than 5\% false positive values, the default statistical acceptance level. Limits are often at the mercy of instrument performance, which can be checked by use of pure standard compounds. Limits of detection and determination are unnecessary for composition specifications although the statistical problem of whether or not a limit is violated is the same near zero as it is at a finite value.

Blank values must be monitored continuously as a control of reagents, cleaning of glassware, and instrument operation. The necessity for a matrix
blank would be characteristic of the matrix. Abrupt changes require investigation of the source and correction. Taylor (J.K. Taylor “Quality Assurance of Chemical Measurements” Lewis Publishers, Chlesea MI, 1987, p. 127) provides two empirical rules for applying a correction in trace analysis: (1) The blank should be no more than 10% of the “limit of error of the measurement”, and (2) it should not exceed the concentration level.

3.4.7 Reporting low-level values

Although on an absolute scale low level values are miniscule, they become important in three situations:

a. When legislation or specifications decrees the absence of an analyte (zero tolerance situation);

b. When very low regulatory or guideline limits have been established in a region of high uncertainty (e.g., a tolerance of 0.005 ug/kg aflatoxin M1 in milk);

c. When dietary intakes of low level nutrients or contaminants must be determined to permit establishment of minimum recommended levels for nutrients and maximum limits for contaminants.

Analytical work in such situations not only strains the limits of instrumentation but also the ability of the analyst to interpret and report the findings. Consider a blank that is truly 0 and that the 10% point of the calibration curve corresponds to a concentration of 1 ug/kg (E-9). By the Horwitz formula this leads to an expected RSD in a single laboratory of about 23%. If we assume a normal distribution and we are willing to be wrong 5% of the time, what concentration levels would be expected to appear? From 2-tail normal distribution tables (the errant value could appear at either end) 2.5% of the values will be below 0.72 ug/kg and 2.5% will be above 1.6 ug/kg. Note the asymmetry of the potential results, from 0.7 to 1.6 ug/kg for a nominal 1.0 ug/kg value from the nature of the multiplicative scale when the RSD is relatively large.

But what does the distribution look like at zero? Mathematically it is intractable because it collapses to zero. Practically, we can assume the distribution looks like the previous one but this time we will assume it is symmetrical to avoid complications. The point to be made will be the same. For a distribution to have a mean equal to 0, it must have negative as well as positive values. But negative concentration values per se are forbidden but here they are merely an artifact of transforming measured signals. Negative signals are typical in electromotive force and absorbance measurements.

Analysts have an aversion to reporting a zero concentration value because of the possibility that the analyte might be present, but below the detection limit. Likewise, analysts avoid reporting negative values as physical impossibilities although they are required by arithmetic averaging of random fluctuations to attain a real zero. Analysts avoid the issue by linguistic subterfuges such as “less than the detection limit” or by substituting an arbitrary
fractional value such as one half the detection limit. Statisticians must discard such values as useless and consequently much effort is simply wasted by such reports.

Therefore the recommendation for handling low level values for validation purposes is to report whatever value is returned by converting the recorded instrument reading to a concentration through the calibration chart: positive, negative, or zero and rely on the power of averaging to produce the best estimate. As stated by the (UK) Analytical Methods Committee (Anal. Tech. Brief No. 5, Apr 2001), “analytical results are not concentrations but error-prone estimates of concentrations.”

Such advice is impractical for reporting to a nontechnical or even a technical reviewer unfamiliar with the statistical problem of reporting results near zero. In such cases, the simplest solution is to report “zero” or “none found” for all signal values within the region of (blank value + 3 x (standard deviation of the blank signal)). This can be supplemented by a statement that the variability of results in the region of zero is such that it would permit as much as x ug/kg to be present with not more than a 5% probability, where x is roughly 5. If the laboratory can calculate the confidence interval of the calibration curve, a better estimate is obtained by drawing a line parallel to the x-axis from the y (signal) value where the upper confidence line intersects the y-axis (y₀) until it intersects the lower confidence line and reading the x (concentration) value (x₀₉₅) of the line parallel to the y-axis where it intersects the x-axis (see Figure 2). This curve can be used to supply a statement that any signal less than y₀ can be reported as “zero” or “none found” with only a 5% chance of being wrong.
Figure 2. The statistical situation at the zero concentration level: A signal as high as $y_0$ could be measured at a 0 concentration which corresponds to a “true” concentration value as high as $x_{95}$, but with only a 5% probability.

### 3.4.8 Dichotomous reporting (Qualitative analysis)

In an effort to bypass the laborious effort to develop and validate a method of analysis, a request is often made to obtain a test that will merely verify the presence or absence of an analyte. Such a request assumes correctly that it is simpler to divide a continuum of measurements of a property into two parts than into more than two parts. This concept assigns all values on one side of the division as acceptable, positive, or present and all values on the other side as unacceptable, absent, or negative. Even assuming that it is easy to set a dividing value through an external specification, tolerance, or limit-setting procedure, we cannot escape the statistical problem of interpretation of a measured value because of the accompanying distribution or halo of uncertainty.

This problem was discussed many years ago in connection with the interpretation of very simple spot tests by Feigl, the developer of this technique (Feigl, F. “Laboratory Manual of Spot Tests” (1943) Academic Press New York).
“If the sensitivity of a spot reaction is checked by progressively diluting a given standard solution, and then at each dilution, one drop is taken for the test, different observers will practically never agree absolutely in their determinations of the identification limit, even though the same experimental conditions have been closely maintained by all. Almost always there will be a certain range of variation.” (p. 4)

We now understand the reason for the “range of variation.” It arises from the statistical distribution of any physical measurement characterized by a location parameter (mean) and a distribution parameter (standard deviation). Any single observation removed from the distribution at the dividing value could have been anywhere within the envelope of that distribution. Half of the observations will be above and half below even though the “true value” of the property is a fixed number. The property may be fixed, but the measurements are variable.

A qualitative test has been defined in terms of indicating if an analyte is present or absent, above or below a limit value, and as a test with “poorer” precision than a quantitative method. But all of these definitions degenerate into the single test of whether a measured value is significantly different (in a statistical sense) from a fixed value.

Consequently when a test is used in a qualitative manner, any anticipated gain in the number of test samples examined at the expense of reliability, is illusionary. The test is fundamentally no different from determining if a found value is above or below a quantitative specification value. When the concentration drops into a region of high measurement variability the signal degenerates from real measurements into false positives for the blanks and false negatives for the measurements.

Nevertheless, the Codex Alimentarius Volume 3 “Residues of Veterinary Drugs in Foods” 2nd ed. (1993), Joint FAP/WHO Food Standards Programme, FAO, Rome Italy, p 55-59, recognizes such methods as a Level III method to determine the presence or absence of a compound “at some designated level of interest.” It anticipates that such methods involve microbiological or immunological principles and they “should produce less than 5 percent false negatives and less than 10 percent false positives when analysis is performed on the test sample.” It is doubtful if the statistical properties (e.g., power) of this recommendation have been examined and if such requirements are achievable with a reasonable number of examinations. A rough calculation indicates that to achieve the required specification more than 200 independent tests on the same test sample would have to be made, a requirement that would probably exhaust the analytical sample before a dozen tests were made.
3.5 Controls

3.5.1 Control charts

Control charts are only useful for large volume or continuous work. They require starting with at least 20-30 values to calculate a mean and a standard deviation, which form the basis for control values equivalent to the mean ± 2 \( s_r \) (warning limits) and the mean ± 3 \( s_r \) (rejection limits). At least replicate test portions of a stable house reference material and a blank are run with every batch of multiple test samples and the mean and standard deviations (or range of replicates) of the controls and blank are plotted separately. The analytical process is “in control” if not more than 5% of the values fall in the warning zone. Any value falling above the rejection limit or two consecutive values in the warning region requires investigation and corrective action.

3.5.2 Injection controls

A limit of 1 or 2 % is often placed on the range of values of the peak heights or areas or instrument response of repeated injections of the final isolated analyte solution. Such controls are good for checking stability of the instrument during the time of checking but give no information as to the suitability of the isolation part of the method. Such a limit is sometimes erroneously quoted as a relative standard deviation when range is meant.

3.5.3 Duplicate controls

Chemists will frequently perform their analyses in duplicate in the mistaken belief that if duplicates check, the analysis must have been conducted satisfactorily. ISO methods often require that the determinations be performed in duplicate. Simultaneous replicates are not independent—they are expected to check because the conditions are identical. The test portions are weighed out using the same weights, aliquots are taken with the same pipets, the same reagents are used, operations are performed within the same time frame, instruments are operated with the same parameters, and the same operations are performed identically. Under such restraints, duplicates that do not check would be considered as outliers. Nevertheless, the parameter calculated from duplicates within a laboratory is frequently quoted as the repeatability limit, \( r \), as equal to

\[ 2\sqrt{2}s_r \]

and is expected to encompass 95% of future analyses conducted similarly. The corresponding parameter comparing 2 values in different laboratories is the reproducibility limit, \( R = 2\sqrt{2}s_R \). This parameter is expected to reflect more independent operations. Note the considerable difference between the standard deviations, \( s_r \) and \( s_R \), an average-type parameter, and the repeatability and reproducibility limits, \( r \) and \( R \), which are 2.8 times larger.
duplicates do not check within the r value, look for a problem — methodological, laboratory, or sample in origin. Note that these limits \( (2^*\sqrt{2} = 2.8) \) are very close to the limits used for rejection in control charts \( 3*s_r \). Therefore they are most useful for large volume routine work rather than for validation of methods. Note the considerable difference between the standard deviations, \( s \) and \( s_{R} \), an average-type parameter, and the repeatability and reproducibility limits, \( r \) and \( R \), which are 2.8 times larger.

### 3.6 Confirmation of Analyte

Because of the existence of numerous chemical compounds, some of which have chemical properties very close to analytes of interest, particularly in chromatographic separations, but different biological, clinical, or toxicological properties, regulatory decisions require that the identity of the analyte of interest be confirmed by an independent procedure. This confirmation of chemical identity is in addition to a quantitative “check analysis”, often performed independently by a second analyst to confirm that the quantity of analyte found in both analyses exceeds the action limit.

Confirmation provides unequivocal evidence that the chemical structure of the analyte of interest is the same as that identified in the regulation. The most specific method for this purpose is mass spectrometry following a chromatographic separation with a full mass scan or identification of 3 or 4 fragments that are characteristic of the analyte sought or the use of multiple mass spectrometric examination (MS\(_n\)). Characteristic bands in the infrared can also serve for identification but this technique usually requires considerably more isolated analyte than is available from chromatographic separations unless special examination techniques are utilized. Visible and ultraviolet spectra are too subject to interferences to be useful, although characteristic peaks can suggest structural characteristics.

Other techniques that can be used for identification, particularly in combination, in approximate order of specificity, include:

- Co-chromatography, where the analyte, when mixed with a standard and then chromatographed by HPLC, GLC, or TLC, exhibits a single entity, a peak or spot with enhanced intensity.
- Characteristic fluorescence (absorption and emission) of the native compound or derivatives.
- Identical chromatographic and spectral properties after isolation from columns of different polarities or with different solvents.
- Identical full-scan visible or ultra-violet spectra, with matching peak(s).

Furthermore, no additional peaks should appear when chromatographic conditions are changed, e.g., different solvents, columns, gradients, temperature, etc.
3.7 Stability of the Analyte

The product should be held under typical or exaggerated storage conditions and the active ingredient(s) assayed periodically for a period of time judged to reasonably exceed the shelf life of the product. In addition, the appearance of new analytes from deterioration should be explored, most easily by a fingerprinting technique, §2.1.

4.0 Report (as applicable)

4.1 Title
Single Laboratory Validation of the Determination of [Analyte] in [Matrix]
by [Nature of Determination]
Author, Affiliation
Other participants

4.2 Applicability (Scope)
Analytes
Common and chemical name
CAS Registry Number or Merck Index Number
Matrices used
In presence of:
In absence of:
Safety statements applicable to product

4.3 Principle
Preparation of test portion
Extraction
Purification
Separation
Measurement
Alternatives
Interferences

4.4 Reagents (reagents usually present in a laboratory need not be listed)
Reference standards, identity, source, purity,
Calibration standard solutions, preparation, storage, stability
Solvents (special requirements)
Buffers
Others

4.5 Apparatus (equipment usually present in a laboratory need not be listed; provide source, WEB address, and catalog numbers of special items)
Chromatographic equipment
Operating conditions
System suitability conditions
- Expected retention times, separation times, peak or area relations
- Temperature controlled equipment
- Separation equipment (centrifuges, filters)
- Measurement instruments

4.6 Calibration
- Range, number and distribution of standards, replication, stability

4.7 Procedure
- List all steps of method, including any preparation of the test sample.
- Critical points
- Stopping points

4.8 Calculation
- Formulae, symbols, significant figures

4.9 Controls

4.10 Results of Validation
4.10.1 Identification data
- Analytes measured and properties utilized
- Matrices tested
- Reference standard, source, identity, purity

4.10.2 Performance data
- Recovery of control material
- Repeatability (by replication of entire procedure on same test sample)
- Limit of determination (Concentration where \( RSD_r = 20\% \) or \((\text{blank} + 10 \times s_{\text{blank}})\)
- Expanded measurement uncertainty \( 2s_r \)

4.10.3 Low level data:
- report instrument reading converted to a concentration through the calibration curve: positive, negative, or zero. Do not equate to 0, do not truncate data, or report “less than”.
- **Interpretation:** Concentrations less than 5 ug/kg may be reported as “zero” or “less than 5 ug/kg” with a 95% probability (5% chance of being incorrect).

4.10.4 Stability data
ANNEX

Abbreviations and symbols used:

- **CAS** Chemical Abstracts Service (Registry Number)
- **CRM** Certified Reference Material
- **FDA** US Food and Drug Administration
- **EPA** US Environmental Protection Agency
- **GLC** Gas-liquid chromatography
- **HPLC** High performance liquid chromatography
- **i** (as a subscript) intermediate in precision terms
- **ISO** International Organization for Standardization (Geneva)
- **MU** Measurement Uncertainty
- **MS** Mass Spectrometry
- **MS_n** Multiple mass spectrometry
- **NMR** Nuclear magnetic resonance
- **r, R** repeatability, reproducibility limits: the value less than or equal to the absolute difference between two test results obtained under repeatability (reproducibility) conditions is expected to be with a probability of 95% = $2\times s_r$ or $2\times s_R$
- **RSDr** repeatability relative standard deviation = $s_r \times 100/$
- **RSDR** reproducibility relative standard deviation = $s_R \times 100/$
- **WEB** Internet address
- **s_r** Repeatability standard deviation (within-laboratories)
- **s_R** Reproducibility standard deviation (among-laboratories)
- **\(\bar{x}\)** Mean, average

APPENDIX

Example of a Ruggedness Trial

Choose 7 factors that may affect the outcome of the extraction and assign reasonable high and low values to them as follows:

<table>
<thead>
<tr>
<th>Factor</th>
<th>High value</th>
<th>Low value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Weight of test portion</td>
<td>A = 1.00 g</td>
<td>a = 0.50 g</td>
</tr>
<tr>
<td>Extraction temperature</td>
<td>B = 30°</td>
<td>b = 20°</td>
</tr>
<tr>
<td>Volume of solvent</td>
<td>C = 100 mL</td>
<td>c = 50 mL</td>
</tr>
<tr>
<td>Solvent</td>
<td>D = alcohol</td>
<td>d = ethyl acetate</td>
</tr>
<tr>
<td>Extraction time</td>
<td>E = 60 min</td>
<td>e = 30 min</td>
</tr>
<tr>
<td>Stirring</td>
<td>F = magnetically</td>
<td>f = swirl 10 min intervals</td>
</tr>
<tr>
<td>Irradiation</td>
<td>G = light</td>
<td>g = dark</td>
</tr>
</tbody>
</table>
Conduct 8 runs (a single analysis that reflects a specified set of factor levels) utilizing the specific combinations of high and low values for the factors as follows, and record the result obtained for each combination. (It is essential that the factors be combined exactly as specified or erroneous conclusions will be drawn.)

<table>
<thead>
<tr>
<th>Run No.</th>
<th>Factor Combinations</th>
<th>Measurement obtained</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>A B C D E F G</td>
<td>x1</td>
</tr>
<tr>
<td>2</td>
<td>A B c D e f g</td>
<td>x2</td>
</tr>
<tr>
<td>3</td>
<td>A b C d E f g</td>
<td>x3</td>
</tr>
<tr>
<td>4</td>
<td>A b c d e F G</td>
<td>x4</td>
</tr>
<tr>
<td>5</td>
<td>a B C d e F g</td>
<td>x5</td>
</tr>
<tr>
<td>6</td>
<td>a B c d E f G</td>
<td>x6</td>
</tr>
<tr>
<td>7</td>
<td>a b C D e f G</td>
<td>x7</td>
</tr>
<tr>
<td>8</td>
<td>a b c D E F g</td>
<td>x8</td>
</tr>
</tbody>
</table>

To obtain the effect of each of the factors, set up the differences of the measurements containing the subgroups of the capital letters and the small letters from column 2 thus:

Effect of A and a  
\[ \frac{(x_1 + x_2 + x_3 + x_4)/4}{4A/4} - \frac{(x_5 + x_6 + x_7 + x_8)/4}{4a/4} = J \]

Note that the effect of each level of each chosen factor is the average of 4 values and that the effects of the 7 other factors cancel out. (The Youden ruggedness trial or fractional factorial experiment was designed for this outcome!) Similarly,

Effect of B and b  
\[ \frac{(x_1 + x_2 + x_5 + x_6)/4}{4B/4} - \frac{(x_3 + x_4 + x_7 + x_8)/4}{4b/4} = K \]

Effect of C and c  
\[ \frac{(x_1 + x_3 + x_5 + x_7)/4}{4C/4} - \frac{(x_2 + x_4 + x_6 + x_8)/4}{4c/4} = L \]

Effect of D and d  
\[ \frac{(x_1 + x_2 + x_7 + x_8)/4}{4D/4} - \frac{(x_3 + x_4 + x_5 + x_6)/4}{4d/4} = M \]

Effect of E and e  
\[ \frac{(x_1 + x_3 + x_6 + x_8)/4}{4E/4} - \frac{(x_2 + x_4 + x_5 + x_7)/4}{4e/4} = N \]

Effect of F and f  
\[ \frac{(x_1 + x_4 + x_5 + x_8)/4}{4F/4} - \frac{(x_2 + x_3 + x_6 + x_7)/4}{4f/4} = O \]

Effect of G and g  
\[ \frac{(x_1 + x_4 + x_6 + x_7)/4}{4G/4} - \frac{(x_2 + x_3 + x_5 + x_8)/4}{4g/4} = P \]
Perform the 8 determinations or runs carefully using the assigned factor level combinations and tabulate the values found. Then unscramble the 7 factors and obtain the effect of the assigned factor as the last number. It is important to use the combination of subscripts as assigned for proper interpretation.

<table>
<thead>
<tr>
<th>Expt.</th>
<th>Found, %</th>
<th>Factors</th>
</tr>
</thead>
<tbody>
<tr>
<td>x1</td>
<td>1.03</td>
<td>J (A) = 4A/4 – 4a/4 = 4.86 – 5.14 = -0.28</td>
</tr>
<tr>
<td>x2</td>
<td>1.32</td>
<td>K (B) = 4B/4 – 4b/4 = 4.79 – 5.21 = -0.42</td>
</tr>
<tr>
<td>x3</td>
<td>1.29</td>
<td>L (C) = 4C/4 – 4c/4 = 4.86 – 5.14 = -0.28</td>
</tr>
<tr>
<td>x4</td>
<td>1.22</td>
<td>M (D) = 4D/4 – 4d/4 = 5.05 – 4.95 = +0.10</td>
</tr>
<tr>
<td>x5</td>
<td>1.27</td>
<td>N (E) = 4E/4 – 4e/4 = 4.92 – 5.08 = -0.16</td>
</tr>
<tr>
<td>x6</td>
<td>1.17</td>
<td>O (F) = 4F/4 – 4f/4 = 4.95 – 5.05 = -0.10</td>
</tr>
<tr>
<td>x7</td>
<td>1.27</td>
<td>P (G) = 4G/4 – 4g/4 = 4.69 – 5.31 = -0.62</td>
</tr>
<tr>
<td>x8</td>
<td>1.43</td>
<td></td>
</tr>
</tbody>
</table>

These values are plotted on a line. In this case they are more or less uniformly scattered along the line, but some attention should be paid to the extremes. Factor D, the highest positive value represents a difference in solvent, as expected, and this factor has to be investigated further to determine if the high values represent impurities or additional active ingredient. The extreme value of factor G suggests that the extraction should be conducted in the dark. As discussed by Youden, considerably more information can be obtained by utilizing several different materials and several independent replications in different laboratories, so as to obtain an estimate of the standard deviation to be expected between laboratories. Although the ruggedness trial is primarily a method development technique, validation of the application of a method to different matrices and related analytes can be explored simultaneously by this procedure.
3.3 Calibration: Run standards from low to high to compensate for any carryover. [Run in random order to compensate for drift is more important than allowing for carryover which should not occur.]

Independently made standards results in considerable random error in the calibration curve and is in fact the major source of random error in spectrophotometry. [Therefore a common stock solution is the preferred way of preparing the individual standards.]

Version 54 contains revisions as a result of comments from levanseler@nsf.org and McClure 301-436-1834

Outline:
I. Types and benefits of each method validation study w/o reproducibility
II. Preparing for a Single Laboratory Method Validation Study
III. Review of performance characteristics of a method
IV. Errors
V. Calibration and types
VI. Bias and Precision estimations
    No reference standard; no reproducibility
VII. Detection and Quantification Limits
VIII. Ruggedness
